Early Tumoricidal Drug-Induced Cardiotoxicity

Determination: Possibilities of Biological Markers

Abstract

Cardiotoxicity due to tumorigenic drug use is defined as an asymptomatic reduction in left ventricular (LV) ejection fraction (EF) of ≥10% to <55% or as a reduction of the LVEF of ≥5% to <55% with symptoms of heart failure (HF). The implementation in routine practices the highly tumoricidal anthracycline drugs, taxanes, and trastuzumab cause progressive LV dysfunction and symptomatic HF in dose-dependent manner. Despite there is potent reversibility of tumoricidal drug-induced cardiotoxicity, this adverse effect frequently consists continuously and might lead to limited response to medical treatment and worse survival sufficiently. The aim of the mini review is consideration the clinical evidence that supports the use of cardiac biomarkers for early detection of cardiotoxicity. The review is reported that the identification of cancer patient with increased risk of early cardiotoxicity would allow not only prevention and diagnosis of chemotherapy related cardiotoxicity but also administration of optimal dose and duration of chemotherapy. The predictive role of brain natriuretic peptides, cardiac troponins and inflammatory biomarkers (C-reactive protein) is discussed.

Keywords: cardiotoxicity; anti-neoplastic chemotherapy; biomarkers; natriuretic peptides; C-reactive protein; troponins; risk stratification

Introduction

Cardiotoxicity as resulting in anti-neoplastic chemotherapy, radiation therapy, and targeted agents is well recognized and frequently considered an expected adverse effect [1]. The implementation in routine practice the highly tumoricidal anthracycline
drugs, taxanes, and trastuzumab cause progressive left ventricular (LV) dysfunction and symptomatic heart failure (HF) in dose-dependent manner [2, 3]. The improved survival rate raises the likelihood that patients will experience wide spectrum cardiotoxicity: from asymptomatic diastolic dysfunction to acute severe HF [4]. Although reversibility of tumoricidal drug-induced cardiotoxicity is possible [5, 6], in generally, this adverse effect frequently consists continuously and might lead to limited response to medical treatment and worse survival sufficiently [7, 8]. Despite the majority of patients with LVEF decline from cancer therapy could achieve full LVEF recovery and complete their cancer therapy, there is no consensual agreement regarding strategy to management cardiac dysfunction in this patient population [9]. Additionally, there are no developed clinical guidelines for early detection of cardiotoxicity too. It has been suggested that biomarkers, most prominently brain natriuretic peptides (BNPs), cardiac troponins and inflammatory biomarkers (C-reactive protein, soluble ST2, galectin-3) might have utility to stratify the patients at risk of potential cardiac dysfunction at early stage before clinically manifestation [10, 11]. The aim of the mini review is consideration the clinical evidence that supports the use of cardiac biomarkers for early detection of cardiotoxicity.

Definition of cardiotoxicity

According Cardiac Review and Evaluation Committee criteria cardiotoxicity due to tumoricidal drug use is generally characterized by an asymptomatic reduction in LVEF of ≥10% to <55% or, less often, as a reduction of the LVEF of ≥5% to <55% with symptoms of HF [12]. The cardiac dysfunction associated with anthracycline therapy leads to significantly decline of LVEF and frequently associates with asymptomatic and symptomatic HF, whereas trastuzumab-induced cardiotoxicity is most often reversible upon discontinuation of treatment and initiation of standard medical care for HF [13, 14].

Molecular pathogenetic mechanisms underlying anthracycline-induced cardiac toxicity

It is well known that pivotal role in anthracycline-induced cardiotoxicity belongs to oxidative stress, which mediates worse of myofilament protein synthesis, destroying structured protein, and cytoskeleton, and as well as apoptosis of cardiac myocytes [15-17]. Therefore, anthracycline is able to suppress reparative capable of cardiac myocytes via inhibition of cardiac progenitor cells mobbing and differentiation [18, 19]. It has been suggested that calcium overload resulting in alterations in cardiac myocytes metabolism leads to ultrastructural changes in cytoskeleton and mediates development of asymptomatic myocardial dysfunction and subsequently clinically manifested HF [20, 21]. Thus, molecules that are able reflect these multiple faces of pathophysiology of cardiotoxicity are considered potent surrogate candidates in biomarkers with diagnostic and predictive value.
Brain natriuretic peptides

Because of assessment of the LVEF fails to detect subtle alterations in cardiac function in chemotherapy-treated patients, BNP could predict future cardiac dysfunction. Current clinical guidelines serve measurement of BNP as a marker of biomechanical stress for diagnostic and predictive value in generally population patients at high risk of HF development and in those who have acute or symptomatic chronic HF with volume overload [22-25]. Theoretically, cardiac dysfunction as result in chemotherapy might reflect in stretching of cardiac wall and secretion of BNP in circulation. However, the received results were controversial and frequently relate to treatment regime, the adjuvant setting and concomitant therapy. Sawaya et al [26] reported that NT-proBNP did not predict cardiotoxicity patients treated with anthracyclines and trastuzumab. Fallah-Rad et al [27] were not able to find sufficient changes in serum concentrations of troponin T, C-reactive protein, and BNP among trastuzumab-treated patients with human epidermal growth factor receptor II-positive (HER2+) breast cancer. Contrary, Cil et al [28] have found a closely association between higher NT-proBNP levels and reduced LVEF in asymptomatic breast cancer patients after doxorubicin administration. Authors have shown that NT-proBNP could be an early indication of subclinical acute anthracycline cardiotoxicity. Ürün et al [29] have believed that women with HER2+ breast cancer treated with trastuzumab could early stratify at risk of cardiotoxicity with of NT-proBNP (> 300 ng/ml). Moreover, Horácek et al [30] have reported that transient elevation of NT-proBNP may indicate acute subclinical cardiotoxicity in anthracycline-treated patients with acute myeloid leukemia. Thus, it seems to be that NT-proBNP could be useful in the early detection of anthracycline cardiotoxicity [31], while trastuzumab-induced cardiotoxicity is probably not defined by measurement of serum NT-proBNP [32].

High-sensitivity cardiac troponins

The results regarding predictive value of high-sensitivity cardiac troponins in anthracycline and trastuzumab cardiotoxicity are controversial. This controversial relates that anthracyclines, even in higher cumulative doses, do not usually cause detectable acute injury to cardiomyocyte structure. Indeed, Horácek et al [32] reported that high-sensitivity cardiac troponin T was not elevated in patients treated for acute leukemia with anthracycline, although serum level of NT-proBNP was elevated sufficiently and could be useful in the early detection of anthracycline cardiotoxicity. In another study, in contrast to BNP, elevated high-sensitivity cardiac troponin I level was proposed an independent predictor of the development of cardiotoxicity at 6 months in cancer patients treated with anthracyclines and trastuzumab [25]. Additionally, there are evidences regarding that the early increase in high-sensitivity cardiac troponin I might offer additive information about the cardiotoxicity risk in cancer patients undergoing doxorubicin and trastuzumab therapy [33-35]. Overall, biochemical markers of
structural and functional myocardial damage, such as cardiac troponins, might have utility in cardiotoxicity monitoring in doxorubicin- and trastuzumab-treated individuals.

**High-sensitivity C-reactive protein**

High-sensitivity C-reactive protein (hs-CRP) is discussed a predictive biomarker of increased risk of cardiotoxicity among cancer patients treated with anthracycline and trastuzumab [36]. Onitilo et al [37] reported that elevated hs-CRP (≥3 mg/L) predicted decreased LVEF with a sensitivity of 92.9% and specificity of 45.7% in patients with early HER2+ breast cancer. Interestingly, author found that the maximum hs-CRP value was observed a median of 78 days prior to detection of cardiotoxicity by decreased LVEF, and those with normal levels were at lower risk for cardiotoxicity. This result opens a perspective to regular monitoring of hs-CRP level for identifying women with early-stage breast cancer at low risk for asymptomatic trastuzumab-induced cardiotoxicity. In contrast, Lipshultz et al [38] did not find closely association increased hs-CRP with any echocardiographic variables in doxorubicin-treated subjects with acute lymphoblastic leukemia, although cardiac troponin T and NT-proBNP were related to an abnormal LV thickness-to-dimension ratio, suggesting LV remodeling. In general, definitive validation studies are required to fully establish clinical utility of hs-CRP in cancer patients as biomarker of cardiotoxicity.

**Future perspectives**

Because of biomechanical stress biomarkers (BNP, NT-proBNP), markers of myocardial injury (cardiac troponin) and inflammation (hs-CRP) are not specific for cardiotoxicity and might not help to sufficiently individualize treatment by immediately identifying cardiac injury and HF, novel biomarkers are discovered widely. It has been suggested that several cardiac biomarkers reflected inflammatory reactions and oxidative stress, i.e. growth differentiation factor-15, myeloperoxidase, and galectin-3, could useful for prediction of the risk of early cardiotoxicity. Probably, biomarkers of angiogenesis (placental growth factor), vascular remodeling (soluble fms-like tyrosine kinase receptor-1) might be demonstrated the benefit in this setting too. In this context, more investigations are required to consolidate our knowledge regarding utility of biomarkers of cardiotoxicity in cancer patients.

**Conclusion**

One can suggest that the identification of cancer patient with increased risk of early cardiotoxicity would allow not only prevention and diagnosis of chemotherapy related cardiotoxicity but also administration of optimal dose and duration of chemotherapy. However, the determining optimal biomarker(s) for risk stratification strategy is not completely clear and requires more investigations.
